SQL: Transactions

Introduction to Databases CompSci 316 Spring 2019

Announcements (Tue., Feb. 26)

- Project Milestone #1 due tonight
 - Please submit one report per group
- Homework 2 problems due on Thursday

Motivation: Concurrent Execution

- Concurrent execution of user programs is essential for good DBMS performance.
 - · Disk accesses are frequent, and relatively slow
 - it is important to keep the CPU busy by working on several user programs concurrently
 - short transactions may finish early if interleaved with long ones
 - may increase system throughput (avg. #transactions per unit time) and decrease response time (avg. time to complete a transaction)
- A user's program may carry out many operations on the data retrieved from the database
 - but the DBMS is only concerned about what data is read/written from/to the database

Transactions

T1: BEGIN A=A+100, B=B-100 END T2: BEGIN A=1.06*A, B=1.06*B END

- A transaction is the DBMS's abstract view of a user program
 - a sequence of reads and write
 - the same program executed multiple times would be considered as different transactions
 - DBMS will enforce some ICs, depending on the ICs declared in CREATE TABLE statements
 - Beyond this, the DBMS does not really understand the semantics of the data. (e.g., it does not understand how the interest on a bank account is computed)

Example

· Consider two transactions:

T1: BEGIN A=A+100, B=B-100 END T2: BEGIN A=1.06*A, B=1.06*B END

- Intuitively, the first transaction is transferring \$100 from B's account to A's account. The second is crediting both accounts with a 6% interest payment
- There is no guarantee that T1 will execute before T2 or vice-versa, if both are submitted together.
- However, the net effect must be equivalent to these two transactions running serially in some order

Example

T1: BEGIN A=A+100, B=B-100 END T2: BEGIN A=1.06*A, B=1.06*B END

Consider a possible interleaving (schedule):

T1: A=A+100, B=B-100 T2: A=1.06*A, B=1.06*B

* This is OK. But what about:

T1: A=A+100, B=B-100 T2: A=1.06*A, B=1.06*B

❖ The DBMS's view of the second schedule:

T1: R(A), W(A), R(B), W(B)
T2: R(A), W(A), R(B), W(B)

Commit and Abort

T1: BEGIN A=A+100, B=B-100 END T2: BEGIN A=1.06*A, B=1.06*B END

- A transaction might commit after completing all its actions
- or it could abort (or be aborted by the DBMS) after executing some actions

Concurrency Control and Recovery

T1: BEGIN A=A+100, B=B-100 END T2: BEGIN A=1.06*A, B=1.06*B END

- Concurrency Control
- (Multiple) users submit (multiple) transactions
 - Concurrency is achieved by the DBMS, which interleaves actions (reads/writes of DB objects) of various transactions
 - user should think of each transaction as executing by itself one-at-a-time
 - The DBMS needs to handle concurrent executions
- Recovery
 - Due to crashes, there can be partial transactions
 - DBMS needs to ensure that they are not visible to other transactions

ACID Properties

- Atomicity
- Consistency
- Isolation
- Durability

Atomicity

T1: BEGIN A=A+100, B=B-100 END T2: BEGIN A=1.06*A, B=1.06*B END

- A user can think of a transaction as always executing all its actions in one step, or not executing any actions at all
 - Users do not have to worry about the effect of incomplete transactions

Consistency

T1: BEGIN A=A+100, B=B-100 END T2: BEGIN A=1.06*A, B=1.06*B END

- Each transaction, when run by itself with no concurrent execution of other actions, must preserve the consistency of the database
 - e.g. if you transfer money from the savings account to the checking account, the total amount still remains the same

Isolation

T1: BEGIN A=A+100, B=B-100 END T2: BEGIN A=1.06*A, B=1.06*B END

- A user should be able to understand a transaction without considering the effect of any other concurrently running transaction
 - even if the DBMS interleaves their actions
 - transaction are "isolated or protected" from other transactions

Durability

T1: BEGIN A=A+100, B=B-100 END T2: BEGIN A=1.06*A, B=1.06*B END

- Once the DBMS informs the user that a transaction has been successfully completed, its effect should persist
 - even if the system crashes before all its changes are reflected on disk

Next, how we maintain all these four properties
But, in detail later

Ensuring Consistency

- e.g. Money debit and credit between accounts
- User's responsibility to maintain the integrity constraints
- DBMS may not be able to catch such errors in user program's logic
 - e.g. if the credit is (debit 1)
- However, the DBMS may be in inconsistent state "during a transaction" between actions
 - which is ok, but it should leave the database at a consistent state when it commits or aborts
- Database consistency follows from transaction consistency, isolation, and atomicity

Ensuring Isolation

- DBMS guarantees isolation (later, how)
- If T1 and T2 are executed concurrently, either the effect would be T1->T2 or T2->T1 (and from a consistent state to a consistent state)
- But DBMS provides no guarantee on which of these order is chosen
- Often ensured by "locks" but there are other methods too

Ensuring Atomicity

- Transactions can be incomplete due to several reasons
 - Aborted (terminated) by the DBMS because of some anomalies during execution
 - in that case automatically restarted and executed anew
 - The system may crash (say no power supply)
 - A transaction may decide to abort itself encountering an unexpected situation
 - e.g. read an unexpected data value or unable to access disks

Ensuring Atomicity

- A transaction interrupted in the middle can leave the database in an inconsistent state
- DBMS has to remove the effects of partial transactions from the database
- DBMS ensures atomicity by "undoing" the actions of incomplete transactions
- DBMS maintains a "log" of all changes to do so

Ensuring Durability

- The log also ensures durability
- If the system crashes before the changes made by a completed transactions are written to the disk, the log is used to remember and restore these changes when the system restarts
- "recovery manager" will be discussed later
 - · takes care of atomicity and durability

Notations

T1: BEGIN A=A+100, B=B-100 END T2: BEGIN A=1.06*A, B=1.06*B END

- Transaction is a list of "actions" to the DBMS
 - includes "reads" and "writes"
 - R_T(O): Reading an object O by transaction T
 - W_T(O): Writing an object O by transaction T
 - also should specify Commit_T (C_T) and Abort_T (A_T)
 - T is omitted if the transaction is clear from the context

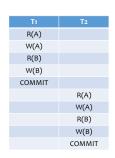

Assumptions

- Transactions communicate only through READ and WRITE
 - i.e. no exchange of message among them
- A database is a fixed collection of independent
 - i.e. objects are not added to or deleted from the database
 - this assumption can be relaxed
 - (dynamic db/phantom problem later)

Schedule

- An actual or potential sequence for executing actions as seen by the DBMS
- A list of actions from a set of transactions
 - includes READ, WRITE, ABORT, COMMIT
- Two actions from the same transaction T MUST appear in the schedule in the same order that they appear in T
 - $\bullet\,$ cannot reorder actions from a given transaction

Serial Schedule

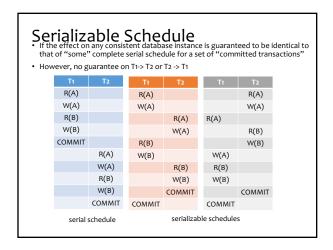

- If the actions of different transactions are not interleaved
 - transactions are executed from start to finish one by one

Problems with a serial schedule

- The same motivation for concurrent executions, e.g.
 - while one transaction is waiting for page I/O from disk, another transaction could use the CPU
 - reduces the time disks and processors are idle
- Increases system throughput
 - average #transactions computed in a given time
- Also improves response time
 - $\bullet\,$ average time taken to complete a transaction
 - since short transactions can be completed with long ones and do not have to wait for them to finish

Scheduling Transactions

- Serial schedule: Schedule that does not interleave the actions of different transactions
- Equivalent schedules: For any database state, the effect (on the set of objects in the database) of executing the first schedule is identical to the effect of executing the second schedule
- Serializable schedule: A schedule that is equivalent to some serial execution of the committed transactions
 - Note: If each transaction preserves consistency, every serializable schedule preserves consistency

Anomalies with Interleaved Execution

- If two consistency-preserving transactions when run interleaved on a consistent database might leave it in inconsistent state
- Write-Read (WR)
- Read-Write (RW)
- Write-Write (WW)
- No conflict with RR if no write is involved

WR Conflict

T1: T2:	R(A), W(A),	R(B), W(B), Abort R(A), W(A), Commit	
T1: T2:	R(A), W(A),	R(B), W(B), Commit R(A), W(A), R(B), W(B), Commit	

- Reading Uncommitted Data (WR Conflicts, "dirty reads"):
 - transaction T2 reads an object that has been modified by T1 but not yet committed
 - or T2 reads an object from an inconsistent database state (like fund is being transferred between two accounts by T1 while T2 adds interests to both)

RW Conflict

T1: R(A), R(A), W(A), C
T2: R(A), W(A), C

- Unrepeatable Reads (RW Conflicts):
 - T2 changes the value of an object A that has been read by transaction T1, which is still in progress
 - If T1 tries to read A again, it will get a different result
 - Suppose two customers are trying to buy the last copy of a book simultaneously

WW conflict

T1: W(A), W(B), C T2: W(A), W(B), C

- Overwriting Uncommitted Data (WW Conflicts, "lost update"):
 - T2 overwrites the value of A, which has been modified by T1, still in progress
 - Suppose we need the salaries of two employees (A and B) to be the same
 - T1 sets them to \$1000
 - T2 sets them to \$2000

Schedules with Aborts

T1: R(A), W(A), Abort T2: R(A), W(A) Commit

- Actions of aborted transactions have to be undone completely
 - may be impossible in some situations
 - say T2 reads the fund from an account and adds interest
 - T1 aims to deposit money but aborts
 - if T2 has not committed, we can "cascade aborts" by aborting T2 as well
 - if T2 has committed, we have an "unrecoverable schedule"

Recoverable Schedule

T1: R(A), W(A), Abort T2: R(A), W(A), R(B), W(B), Commit

- Transaction commits if and only after all transactions they read have committed
 - · avoids cascading aborts

ACID: Summary

- A transaction is a sequence of database operations with the following properties (ACID):
 - Atomic: Operations of a transaction are executed all-ornothing, and are never left "half-done"
 - Consistency: Assume all database constraints are satisfied at the start of a transaction, they should remain satisfied at the end of the transaction
 - Isolation: Transactions must behave as if they were executed in complete isolation from each other
 - Durability: If the DBMS crashes after a transaction commits, all effects of the transaction must remain in the database when DBMS comes back up

SQL transactions

- A transaction is automatically started when a user executes an SQL statement
- Subsequent statements in the same session are executed as part of this transaction
 - Statements see changes made by earlier ones in the same transaction
 - Statements in other concurrently running transactions do not
- COMMIT command commits the transaction
 - Its effects are made final and visible to subsequent transactions
- ROLLBACK command aborts the transaction
 - Its effects are undone

Fine prints

- Schema operations (e.g., CREATE TABLE) implicitly commit the current transaction
 - Because it is often difficult to undo a schema operation
- Many DBMS support an AUTOCOMMIT feature, which automatically commits every single statement
 - You can turn it on/off through the API
 - For PostgreSQL:
 - psql command-line processor turns it on by default
 - You can turn it off at the psql prompt by typing: \set AUTOCOMMIT 'off'

SQL isolation levels

- Strongest isolation level: SERIALIZABLE
 - Complete isolation
- Weaker isolation levels: REPEATABLE READ, READ COMMITTED, READ UNCOMMITTED
 - Increase performance by eliminating overhead and allowing higher degrees of concurrency
 - Trade-off: sometimes you get the "wrong" answer

READ UNCOMMITTED

- · Can read "dirty" data
 - A data item is dirty if it is written by an uncommitted transaction
- Problem: What if the transaction that wrote the dirty data eventually aborts?
- Example: wrong average

• -- T1: -- T2:

UPDATE User SET pop = 0.99

WHERE uid = 142; SELECT AVG(pop) FROM User;

ROLLBACK;

COMMIT;

READ COMMITTED

- No dirty reads, but non-repeatable reads possible
 - Reading the same data item twice can produce different results
- Example: different averages

WHERE uid = 142;

COMMIT;

• -- T1: -- T2: SELECT AVG(pop) FROM User; UPDATE User SET pop = 0.99

SELECT AVG(pop) FROM User; COMMIT;

REPEATABLE READ

- Reads are repeatable, but may see phantoms
- Example: different average (still!)
 - T1:

 -- T2:

 SELECT AVG(pop)
 FROM User;

 INSERT INTO User
 VALUES(789, 'Nelson',
 10, 0.1);
 COMMIT;

SELECT AVG(pop) FROM User; COMMIT;

Summary of SQL isolation levels

Isolation level/anomaly	Dirty reads	Non-repeatable reads	Phantoms
READ UNCOMMITTED	Possible	Possible	Possible
READ COMMITTED	Impossible	Possible	Possible
REPEATABLE READ	Impossible	Impossible	Possible
SERIALIZABLE	Impossible	Impossible	Impossible

- Syntax: At the beginning of a transaction, SET TRANSACTION ISOLATION LEVEL isolation_level [READ ONLY | READ WRITE];
 - READ UNCOMMITTED can only be READ ONLY
- PostgreSQL defaults to READ COMMITTED

Transactions in programming

Using pyscopg2 as an example:

- isolation_level defaults to READ COMMITTED
- read only defaults to False
- · autocommit defaults to False
- When autocommit is False, commit/abort current transaction as follows:

conn.commit()
conn.rollback()

ANSI isolation levels are lock-based

- READ UNCOMMITTED
 - Short-duration locks: lock, access, release immediately
- READ COMMITTED
 - Long-duration write locks: do not release write locks until commit
- REPEATABLE READ
 - Long-duration locks on all data items accessed
- SERIALIZABLE
 - Lock ranges to prevent insertion as well

Isolation levels not based on locks?

Snapshot isolation in Oracle

- Based on multiversion concurrency control
 - Used in Oracle, PostgreSQL, MS SQL Server, etc.
- How it works
 - Transaction X performs its operations on a private snapshot of the database taken at the start of X
 - *X* can commit only if it does not write any data that has been also written by a transaction committed after the start of *X*
- Avoids all ANSI anomalies
- But is NOT equivalent to SERIALIZABLE because of write skew anomaly

Write skew example

- Constraint: combined balance $A + B \ge 0$
- A = 100, B = 100
- T_1 checks $A+B-200 \ge 0$, and then proceeds to withdraw 200 from A
- T_2 checks $A+B-200 \ge 0$, and then proceeds to withdraw 200 from B
- Possible under snapshot isolation because the writes (to A and to B) do not conflict
- But A + B = -200 < 0 afterwards!
- To avoid write skew, when committing, ensure the transaction didn't read any object others wrote and committed after this transaction started

Bottom line

- Group reads and dependent writes into a transaction in your applications
 - E.g., enrolling a class, booking a ticket
- \bullet Anything less than SERIALABLE is potentially very dangerous
 - Use only when performance is critical
 - READ ONLY makes weaker isolation levels a bit safer
